

## *Part 1 Learning Objective Summary*

The output varies depending on the implementation of the code..

If I implement the `pthread_join` call.. and wait for each thread to exit in order.. the the data is access in order and simply increments by 1 each time the global variable is accessed. However, when I don't wait for each thread to wait in order, the global variable is accessed by multiple threads at the same time causing synchronization issues(A race condition). The data result we see from one thread is completely independent of the result we see from the following thread. thread 1 might show 15 and thread 2 might show 12, even though it should have added consecutively.

In summary, the scheduler could start threads before another thread completes, therefore without any synchronization measures including a `pthread_join`, the global variable could have been modified by thread 2 before thread 1 completes.... causing thread 1 to produce an invalid variable result- or the other way around contingent on how the scheduler. With a mutex lock, a secondary thread cannot have access to the variable that the first thread is modifying, therefore no other thread will be able to change the value of a variable ensuring synchronized access of shared resources in the code.A mutex lock is one way of controlling a commonly shared variables between multiple concurrently running threads. Implementing the barrier before the `print` statement allowed all threads to finish before continuing and printing the result.

### DMESG OUTPUT
